Ants Can Solve Constraint Satisfaction Problems

Christine Solnon

***Abstract*—In this paper, we describe a new incomplete approach for solving constraint satisfaction problems (CSPs) based on the ant colony optimization (ACO) metaheuristic. The idea is to use artificial ants to keep track of promising areas of the search space by laying trails of pheromone. This pheromone information is used to guide the search, as a heuristic for choosing values to be assigned to variables. We first describe the basic ACO algorithm for solving CSPs and we show how it can be improved by combining it with local search techniques. Then, we introduce a preprocessing step, the goal of which is to favor a larger exploration of the search space at a lower cost, and we show that it allows ants to find better solutions faster. Finally, we evaluate our approach on random binary problems.**

***Index Terms*—Ant colony optimization (ACO), constraint satisfaction problems (CSPs), local search.**

I. Introduction

SOLVING constraint satisfaction problems (CSPs) involves finding an assignment of values to variables that satisfies a set of constraints. This general problem has many real-life applications, such as scheduling, resource allocation, pattern regognition, and machine vision.

To solve CSPs, one may explore the search space in a systematic and complete way, until either a solution is found or the problem is proven to have no solution [31]. In order to reduce the search space, this kind of complete approach is usually combined with filtering techniques that narrow the variables domains with respect to some partial consistencies. Completeness is a very desirable feature, but it often becomes intractable on hard combinatorial problems. This is particularly true when filtering techniques cannot reduce domains enough to make complete search feasible. Hence, incomplete approaches have been proposed that leave out exhaustivity, trying to quickly find approximately optimal solutions in an opportunistic way. In these approaches, the search space is usually explored stochastically, using heuristics to guide the search toward the most promising areas.

In this paper, we describe an incomplete approach for solving CSPs based on the ant colony optimization (ACO) metaheuristic [7], [8]. The idea is to keep track of promising areas of the search space, by laying "pheromone" trails. This pheromone information is used to guide the search, as a heuristic for choosing values to be assigned to variables.

A. Ant Colony Optimization Metaheuristic

ACO is a stochastic approach that has been proposed to solve different hard combinatorial optimization problems such as traveling salesman problems [6], [9], [10], graph coloring problems [4], quadratic assignment problems [12], [20], and vehicle routing problems [1], [13]. The main idea of ACO is to model the problem as the search for a minimum cost path in a graph. Artificial ants walk through this graph, looking for good paths. Each ant has a rather simple behavior so that it will typically only find rather poor-quality paths on its own. Better paths are found as the emergent result of the global cooperation among ants in the colony.

The behavior of artificial ants is inspired from real ants: they lay pheromone trails on the graph edges and choose their path with respect to probabilities that depend on pheromone trails and these pheromone trails progressively decrease by evaporation. In addition, artificial ants have some extra features that do not find their counterpart in real ants. In particular, they live in a discrete world (a graph) and their moves consist of transitions from nodes to nodes. Also, they are usually associated with data structures that contain the memory of their previous actions. In most cases, pheromone trails are updated only after having constructed a complete path and not during the walk, and the amount of pheromone deposited is usually a function of the quality of the path. Finally, the probability for an artificial ant to choose an edge often depends not only on pheromones, but also on some problem-specific local heuristics.

B. Motivations and Overview of the Paper

When using the ACO metaheuristic to solve a new combinatorial optimization problem, one of the main tasks is to model the problem as the search of a feasible minimum cost path over a weighted graph, where feasibility is defined with respect to a set of constraints. In most cases, these constraints are satisfied in an *a priori* way, i.e., ants only construct "feasible" paths that never violate constraints: at each step of the walk, the next vertex to visit is chosen within a set of feasible candidates (the neighborhood) that only contains vertices that are actually consistent with respect to the constraints of the problem. This set of feasible candidates is supposed never to be empty so that ants are always able to construct feasible paths. For example, in the traveling salesman problem, the constraints impose that each city must appear exactly once in any feasible solution. Therefore, each ant maintains a list of visited cities, and at each step of the walk, it chooses the next city to visit among the set of cities that have not yet been visited.

However, this kind of *a priori* constraint satisfaction may only be applied to loosely constrained problems, when the difficulty is not to find feasible solutions, but the best feasible one with respect to some given objective function. This paper investigates ACO capabilities for solving CSPs, i.e., the goal is no longer to optimize an objective function under some constraints, but to find an assignment that actually satisfies all the constraints. A

main motivation underlying this paper is to provide a generic tool to handle a whole class of problems. Hence, the proposed algorithm may be used to solve any CSP in a generic way.

The paper is organized as follows. In Section II, we introduce some definitions and terminology about CSPs and we recall some results on phase transitions. Section III describes the basic ACO algorithm for solving CSPs, called Ant-Solver. Sections IV and V show how Ant-Solver can be improved by integrating local search (LS) techniques and by introducing a preprocessing step. Finally, Section VI reports experimental results on random binary CSPs and Section VII compares our paper with some other related approaches and discusses future work.

II. Background

A. Constraint Satisfaction Problems

A CSP [31] is defined by a triple (X, D, C) such that X is a finite set of variables, D is a function that maps every variable $X_i \in X$ to its domain $D(X_i)$, i.e., the finite set of values that can be assigned to X_i, and C is a set of constraints, i.e., relations between some variables which restrict the set of values that can be assigned simultaneously to these variables.

An assignment $\mathcal{A} = \{\langle X_1, v_1\rangle, \ldots, \langle X_k, v_k\rangle\}$ is a set of variable-value pairs and corresponds to the simultaneous assignment of values $v_1, \ldots, v_k$ to variables $X_1, \ldots, X_k$, respectively. An assignment $\mathcal{A}$ violates a constraint $c_i \in C$ if each variable involved in c_i is assigned in $\mathcal{A}$ and the relation defined by c_i is not satisfied when replacing each variable of c_i by its associated value in $\mathcal{A}$. The cost of an assignment $\mathcal{A}$, denoted by $\mathrm{cost}(\mathcal{A})$, is defined by the number of constraints that are violated by $\mathcal{A}$. A solution of a CSP (X, D, C) is a complete assignment for all the variables in X, which satisfies all the constraints in C, i.e., a complete assignment with zero cost.

Most real-life CSPs are overconstrained, so that no solution exists. Hence, the CSP framework has been generalized to max-CSPs [11]. In this case, the goal is no longer to find a consistent solution, but to find a complete assignment that maximizes the number of satisfied constraints. Hence, a solution of a max-CSP is a complete assignment with minimal cost. In this paper, we implicitly solve max-CSPs. Artificial ants naturally solve optimization problems. In our context of constraint satisfaction, they aim at minimizing the number of violated constraints. This approach could also be extended to valued CSPs [26] in a rather straightforward way.

B. Random Binary CSPs

Binary CSPs only have binary constraints, i.e., each constraint involves two variables exactly. Binary CSPs may be generated at random. A class of randomly generated CSPs is characterized by four components $\langle n, m, p_1, p_2\rangle$, where n is the number of variables, m is the number of values in each variable domain, $p_1 \in [0, 1]$ is a measure of the connectivity (p_1 determines the number of constraints), and $p_2 \in [0, 1]$ is a measure of the tightness of the constraints (p_2 determines the number of incompatible pairs of values for each constraint).

Experiments reported in this paper were obtained with random binary CSPs generated according to model A as described in [19], i.e., for each pair of distinct variables, we add a constraint between them with probability p_1 and then for each constraint, we rule out a pair of values for the two constrained variables with probability p_2. As incomplete approaches cannot detect inconsistency, we report experiments performed on feasible instances only, i.e., CSPs that do have at least one solution. To generate feasible instances, we first generate a solution randomly and then, for each constraint, we forbid ruling out pairs of values that belong to the generated solution.

C. Phase Transitions

When considering a class of combinatorial problems, rapid transitions in solvability may be observed as an order parameter is changed [2]. These "phase transitions" occur when evolving from instances that are underconstrained and, therefore, solved rather easily, to instances that are overconstrained, whose inconsistency is thus proven rather easily. Harder instances usually occur between these two kinds of "easy" instances, when approximately 50% of the instances are satisfiable.

In order to predict the phase-transition region, [14] introduces the notion of "constrainedness" of a class of problems κ and shows that when κ is close to one, instances are critically constrained, and belong to the phase-transition region. For a class of random binary CSPs $\langle n, m, p_1, p_2\rangle$, [3] defines this constrainedness by $\kappa = ((n - 1/2)p_1 \log_m(1/1 - p_2))$.

One might think that phase transitions only concern complete approaches, as they are usually associated with transitions from solvable to unsolvable instances, and incomplete approaches cannot detect unsolvability. However, different studies (e.g., [3], [5]) have shown that very similar phase-transition phenomena may also be observed with incomplete approaches such as LS.

III. Description of Ant-Solver

Ant-Solver, the proposed algorithm for solving CSPs, follows the classical ACO algorithmic scheme for static combinatorial optimization problems [7], [8] and is shown in Fig. 1. At each cycle, each ant constructs a complete assignment and then pheromone trails are updated. The algorithm stops iterating either when an ant has found a solution or when a maximum number of cycles has been performed. In this section, we first define the construction graph on which artificial ants lay pheromone trails and we describe pheromone initialization. Then, we describe the assignment construction and the pheromone updating steps. Finally, we discuss setting parameters.

A. Construction Graph and Pheromone Trails Initialization

The graph on which artificial ants lay pheromone, called the construction graph, associates a vertex with each variable-value

procedure Construct assignment $\mathcal{A}$ for CSP (X, D, C)
  $\mathcal{A} \leftarrow \emptyset$
  while $|\mathcal{A}| < |X|$ **do**
    Select a variable $X_j \in X$ that is not assigned in $\mathcal{A}$
    Choose a value $v \in D(X_j)$ with probability $p_{\mathcal{A}}(<X_j, v>)$
    $\mathcal{A} \leftarrow \mathcal{A} \cup \{<X_j, v>\}$
  end

Fig. 2. Assignment construction algorithmic scheme.

pair $\langle X_i, v\rangle$ of the CSP. There is an edge between any pair of vertices corresponding to two different variables. More formally, the construction graph associated with a CSP (X, D, C) is the nondirected graph $G = (V, E)$ such that

$$V = \{\langle X_i, v\rangle \mid X_i \in X \text{ and } v \in D(X_i)\}$$
$$E = \{(\langle X_i, v\rangle, \langle X_j, w\rangle) \in V^2 \mid X_i \neq X_j\}.$$

Ants communicate by laying pheromone on graph edges. The amount of pheromone on edge $(\langle X_i, v\rangle, \langle X_j, w\rangle)$ is noted $\tau(\langle X_i, v\rangle, \langle X_j, w\rangle)$. Intuitively, this amount of pheromone represents the learnt desirability of assigning value v to variable X_i and value w to variable X_j simultaneously. Notice that since the graph is not directed, $\tau(\langle X_i, v\rangle, \langle X_j, w\rangle) = \tau(\langle X_j, w\rangle, \langle X_i, v\rangle)$.

As proposed in the $\mathcal{MAX}$-$\mathcal{MIN}$ Ant System [30], we explicitly impose lower and upper bounds $\tau_{\min}$ and $\tau_{\max}$ on pheromone trails (with $0 < \tau_{\min} < \tau_{\max}$). The goal is to favor a larger exploration of the search space by preventing the relative differences between pheromone trails from becoming too extreme during processing. Also, pheromone trails are set to $\tau_{\max}$ at the beginning of the algorithm, thus, achieving a higher exploration of the search space during the first cycles. In Section V, we shall propose to introduce a preprocessing step in order to initialize pheromone trails more suitably and speed up convergence.

B. Construction of Assignments by Ants

The construction of complete assignments by ants is described in Fig. 2. Ants start with an empty assignment and then iteratively select a variable to be assigned and choose a vertex in the graph corresponding to a value assignment for this variable, until all variables have been assigned. The selection of a variable (described in Section III-B1) is performed with respect to some given procedure, whereas the choice of a value for the variable (described in Section III-B2) is made probabilistically, depending on pheromone trails.

Notice that by selecting a variable before choosing a value for it, the set of candidate vertices at each step—the neighborhood—is restricted to the set of all possible values for a single variable, instead of the set of all possible values for all unassigned variables. Such a restriction of the neighborhood is motivated mainly by the fact that the computation of transition probabilities is significantly more expensive than for other applications, such as the traveling salesman problem or the quadratic assignment problem.

1) Selection of a Variable: When constructing an assignment, the order in which the variables are assigned is rather important, as the satisfaction of a constraint can only be checked once all its variables have been assigned. Variable-ordering heuristics have been studied widely [27], [31]. Some commonly used variable orderings are the following: 1) most constraining first ordering, which selects an unassigned variable that is connected (by a constraint) to the largest number of unassigned variables; 2) most constrained first ordering, which selects an unassigned variable that is connected (by a constraint) to the largest number of assigned variables; 3) smallest domain ordering, which selects an unassigned variable that has the smallest number of consistent values with respect to the partial assignment already built; or 4) random ordering, which randomly selects an unassigned variable.

To solve a CSP with Ant-Solver, one has to implement the variable selection procedure which, given a partial assignment, returns the next variable to be assigned. In all experiments reported in this paper, we have used the smallest domain ordering.

2) Choice of a Value: Once a variable has been selected, ants have to choose a value for it. The goal is to choose the "most promising" value for the variable, i.e., the one that will participate in the smallest number of conflicts in the final complete assignment. However, if it is straightforward to evaluate the number of conflicts with the already assigned variables, it is more difficult to anticipate the consequences of the choice of a value on the further assignments of the remaining unassigned variables. Hence, there are very few heuristics for guiding this choice and these heuristics usually are problem-dependent, so they cannot be applied to general CSPs (e.g., [27] for the car-sequencing problem).

The main contribution of ACO for solving CSPs is to provide a general heuristic for choosing values: this choice is made randomly with a probability that depends on a pheromone factor (to evaluate the learnt desirability of the value) and a heuristic factor (to locally evaluate its quality). More formally, let us consider an ant that has already visited a set $\mathcal{A}$ of vertices and whose next selected variable to be assigned is X_j. The probability for this ant to select vertex $\langle X_j, v\rangle$ is defined proportionally to the attraction capability of this vertex with respect to all candidate vertices $\langle X_j, w\rangle$ such that $w \in D(X_j)$

$$p_{\mathcal{A}}(\langle X_j, v\rangle) = \frac{[\tau_{\mathcal{A}}(\langle X_j, v\rangle)]^{\alpha}[\eta_{\mathcal{A}}(\langle X_j, v\rangle)]^{\beta}}{\sum_{w \in D(X_j)} [\tau_{\mathcal{A}}(\langle X_j, w\rangle)]^{\alpha}[\eta_{\mathcal{A}}(\langle X_j, w\rangle)]^{\beta}}$$

where $\tau_{\mathcal{A}}(\langle X_j, v\rangle)$ is the pheromone factor of $\langle X_j, v\rangle$, $\eta_{\mathcal{A}}(\langle X_j, v\rangle)$ is its heuristic factor, and α and β are the parameters that determine their relative weights.

A main difference with many ACO algorithms is that pheromone and heuristic factors do not only depend on some local relation between the candidate vertex $\langle X_j, v\rangle$ and the last visited vertex in $\mathcal{A}$, but on a global relation between the candidate vertex $\langle X_j, v\rangle$ and the whole set $\mathcal{A}$ of visited vertices. Indeed, when choosing a value for X_j, all assignments stored previously in $\mathcal{A}$ are equally important. Therefore, the pheromone factor $\tau_{\mathcal{A}}(\langle X_j, v\rangle)$ depends on all pheromones laid on all edges between $\langle X_j, v\rangle$ and the visited vertices in $\mathcal{A}$

$$\tau_{\mathcal{A}}(\langle X_j, v\rangle) = \sum_{\langle X_k, m\rangle \in \mathcal{A}} \tau(\langle X_k, m\rangle, \langle X_j, v\rangle).$$

The heuristic factor $\eta_{\mathcal{A}}(\langle X_j, v\rangle)$ also depends on the whole set $\mathcal{A}$ of visited vertices. It is inversely proportional to the number of new violated constraints when assigning v to X_j

$$\eta_{\mathcal{A}}(\langle X_j, v\rangle) = \frac{1}{1+\text{cost}(\{\langle X_j, v\rangle\} \cup \mathcal{A}) - \text{cost}(\mathcal{A})}.$$

C. Updating Pheromone Trails

After every ant has constructed a complete assignment, pheromone trails are updated according to ACO: all pheromone trails are decreased uniformly, in order to simulate evaporation and allow ants to forget bad assignments, and then the best ants of the cycle deposit pheromone. More formally, at the end of each cycle, the quantity of pheromone on each edge (i, j) is updated as follows:

$$\tau(i,j) \leftarrow (1-\rho)\cdot\tau(i,j) + \sum_{\mathcal{A}_k \in \text{BestOfCycle}} \Delta\tau(\mathcal{A}_k, i, j)$$

$$\text{if } \tau(i,j) < \tau_{\min}, \text{ then } \tau(i,j) \leftarrow \tau_{\min}$$

$$\text{if } \tau(i,j) > \tau_{\max}, \text{ then } \tau(i,j) \leftarrow \tau_{\max}$$

where ρ is the evaporation parameter such that $0 \leq \rho \leq 1$, BestOfCycle is the set of the best assignments constructed during the cycle, i.e.,

$$\text{BestOfCycle} = \{\mathcal{A}_i \in \{\mathcal{A}_1, \ldots, \mathcal{A}_{\text{nbAnts}}\} \mid \text{cost}(\mathcal{A}_i) \text{is minimal}\}$$

and $\Delta\tau(\mathcal{A}_k, i, j)$ is the quantity of pheromone deposited on edge (i, j) by the ant that has built assignment $\mathcal{A}_k$

$$\Delta\tau(\mathcal{A}_k, i, j) = \frac{1}{\text{cost}(\mathcal{A}_k)}, \text{ if } \{i, j\} \subseteq \mathcal{A}_k$$

$$\Delta\tau(\mathcal{A}_k, i, j) = 0, \quad \text{otherwise.}$$

Contrary to many ACO algorithms, ants deposit pheromone not only on the edges belonging to the path they followed, but on all edges between any pair of visited vertices, i.e., on all edges belonging to the clique defined on the set of visited vertices. The quantity of pheromone laid is inversely proportional to the assignment cost, so that the more constraints are violated, the less pheromone is deposited.

D. Parameters Setting

Ant-Solver is parameterized by α, β, ρ, and nbAnts. We now briefly study the influence of these parameters with respect to two criteria: the success rate, i.e., the percentage of runs that find a solution, and the time spent to find a solution.

The number of ants nbAnts is set to eight: with smaller values, success rates are decreased (as the best assignments constructed at each cycle usually have higher costs); with greater values, running times increase while success rates are not improved (as the best assignments found at each cycle are not significantly better than with eight ants).

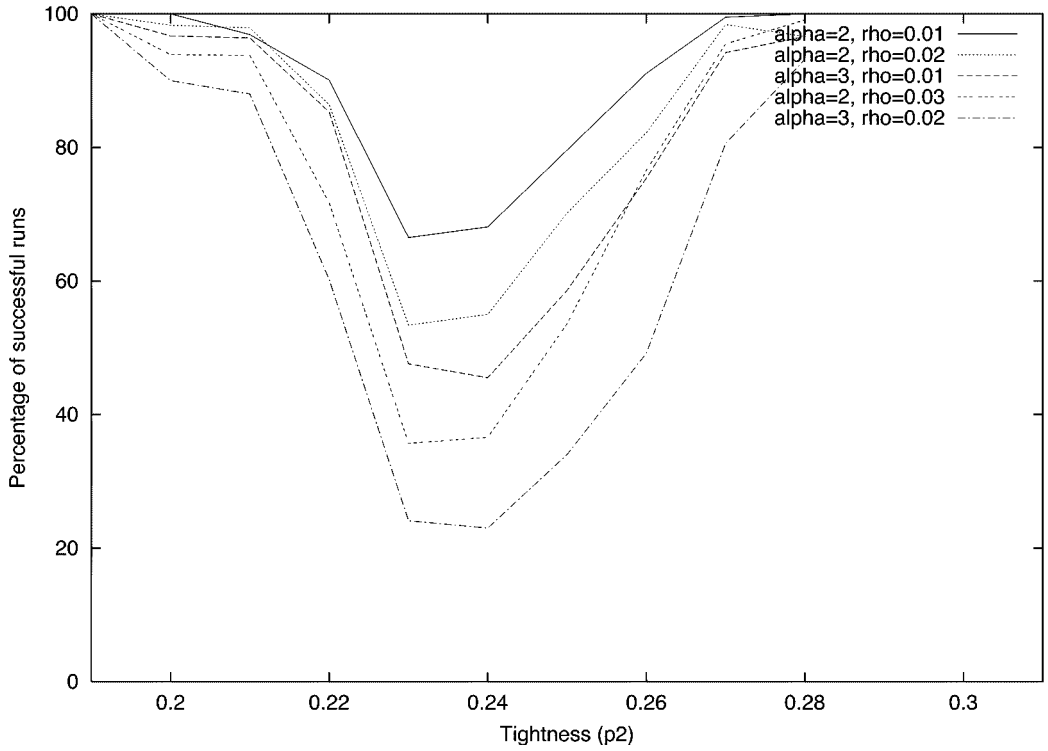
β determines the weight of heuristic factors when computing transition probabilities. It is set to ten: with smaller values, ants globally find worse assignments and it takes them longer to reach a solution.

α determines the weight of pheromone factors in the computation of transition probabilities and ρ determines pheromone evaporation. Both parameters have an influence on the exploratory behavior of ants: to emphasize exploration, one may decrease α (so that ants become less sensitive to pheromone when they choose values) or decrease ρ (so that pheromone evaporates more slowly and relative differences between pheromone trails increase more slowly). When emphasizing exploration of the search space in this way, success rates are improved, but as a counterpart running times are increased. This is illustrated in Fig. 3 on $\langle 100, 8, 0.14, p_2\rangle$ CSPs. As a conclusion, when setting α and ρ, one can either choose values that favor pheromone guidance—such as $\alpha = 3$ and $\rho = 0.02$—or values that favor exploration—such as $\alpha = 2$ and $\rho = 0.01$. In the former case, Ant-Solver will quickly find rather good assignments, but it may not find a solution. In the latter case, Ant-Solver will need more time to find good assignments, but it will more often succeed in finding a solution. One should note that this holds for the various tightness values p_2, although it is more emphasized for the hardest instances.

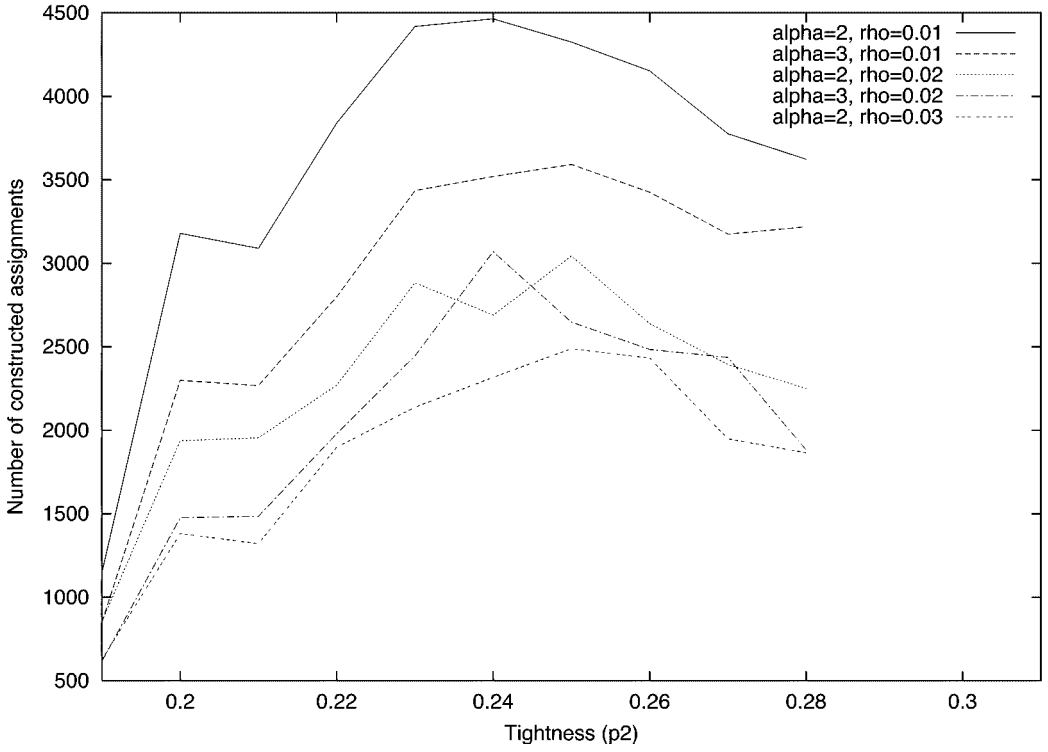
IV. Boosting Ant-Solver With Local Search

Local Search (LS) has shown to be effective to solve large CSPs, e.g., the "million queens problem" in [23]. The basic idea is to construct a complete assignment and then gradually and iteratively repair it by changing some variable-value assignments. LS may be combined with the ACO metaheuristic in a very straightforward way: ants construct assignments, exploiting pheromone trails, and LS improves their quality by iteratively performing local moves. Actually, the best performing ACO algorithms for many combinatorial optimization problems are hybrid algorithms that combine probabilistic solution construction by a colony of ants with LS [9], [30]. In this section, we propose to combine LS with Ant-Solver. In this case, one can view Ant-Solver as a way of taking benefit of the different locally optimal assignments found previously by LS in order to guide it toward the most promising areas of the search space when constructing new assignments to be repaired.

The hybrid algorithm is derived from the algorithm of Fig. 1 as follows: once each ant has constructed an assignment, and before updating pheromone trails, we apply a LS procedure to improve the assignment constructed. Various LS procedures may be used to improve assignments (see, e.g., [16] for an experimental comparison of some of them). However, as pointed out in [18], when choosing the LS procedure to use in a metaheuristic, such as evolutionary algorithms, iterated LS or ACO, one has to find a tradeoff between computation time and solution quality. In other words, one has to choose between a fast, but not-so-good LS procedure or a slower, but more powerful one. For all experiments reported in this paper, we have used a LS procedure based on the min-conflicts heuristic (MCH) [23]. More precisely, at each step, we choose a conflicting variable (involved in some violated constraints) randomly and then we choose a value for this variable which minimizes the number of conflicts. This repair procedure stops iterating when the number of violated constraints is not improved after $\mid X \mid$ successive iterations.



(a)



(b)

Fig. 3. Influence of α and ρ on (a) the success rate and (b) the number of constructed assignments when solving $\langle 100, 8, 0.14, p_2 \rangle$ CSPs (average results on 300 instances for each value of p_2). (a) With respect to the success rate criterion, the best results are obtained when $\alpha = 2, \rho = 0.01$, then when $\alpha = 2, \rho = 0.02$, then when $\alpha = 3, \rho = 0.01$, then when $\alpha = 2, \rho = 0.03$, and the worst results when $\alpha = 3, \rho = 0.02$. (b) With respect to the time criterion (which is proportional to the number of constructed assignments), the best results are obtained when $\alpha = 2, \rho = 0.03$, then when $\alpha = 3, \rho = 0.02$, then when $\alpha = 2, \rho = 0.02$, then when $\alpha = 3, \rho = 0.01$, and the worst when $\alpha = 2, \rho = 0.01$.

Fig. 4 shows the evolution of average costs during processing for five different runs of Ant-Solver and five different runs of Ant-Solver with MCH LS, on a same instance (with $\alpha = 2$, $\beta = 10$, $\rho = 0.01$, and $\mathrm{nbAnts} = 8$). For the five runs of Ant-Solver, the average number of violated constraints decreases from more than 20 at the beginning of the search to less

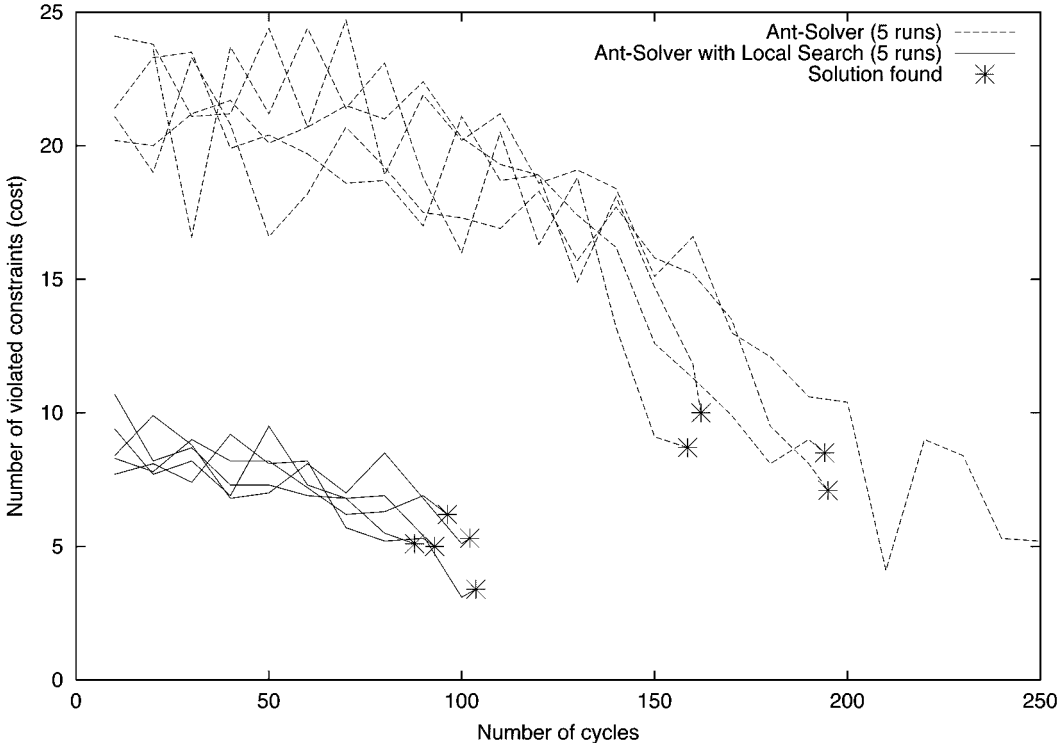


Fig. 4. Evolution of the average number of violated constraints by cycle on a $\langle 100, 8, 0.14, 22\rangle$ instance (with $\alpha = 2$, $\beta = 10$, $\rho = 0.01$, and $\mathrm{nbAnts} = 8$). Dotted lines correspond to five different runs of Ant-Solver. Continued lines correspond to five different runs of Ant-Solver with MCH LS.

than ten after 150 cycles. Finally, in four runs at least one ant has found a solution, between cycle 150 and cycle 200, whereas in the fifth run, none of the ants was able to find a solution. Differently, when combining Ant-Solver with MCH LS, ants find far better assignments from the first cycle on: the average number of violated constraints decreases from nine at the beginning of the search to less than five at cycle 90. Finally, in all the five runs, a solution was found before cycle 110. This shows that LS actually improves the solution process, with respect to both success rates and running times. More experimental results are reported in Section VI.

V. Boosting Ant-Solver With Preprocessing

When exploring the search space in a stochastic way, one usually has to find a tradeoff between two antagonistic goals. On the one hand, one has to guide the search toward "promising" areas of the search space, usually close to the best solutions found so far. Indeed, a study of the shape of the search space shows that for some combinatorial optimization problems (such as the traveling salesman or the quadratic assignment problems) better local optima tend to be closer to global optima [30]. Actually, this property underlies the motivation of evolutionary approaches, which are of little interest in situations for which the correlation between solution fitness and the distance to optimal solutions is too low [17], [21].

On the other hand, one also has to favor a large exploration of the search space in order to discover new and hopefully more successful areas of the search space. Diversifying the search is particularly important during the first cycles in order to avoid premature convergence—search stagnation—toward local optima. As pointed out previously, this exploratory ability of ants can be emphasized both by decreasing α and ρ. However, in this way the algorithm converges more slowly and it takes longer to find a solution.

In this section, we first study the evolution of the influence of pheromone on ants during processing with respect to the cost of administrating it. We then propose to introduce a preprocessing step that favors a larger exploration of the search space at a lower cost, so that more solutions can be found in a shorter time.

A. Impact Versus Cost of Pheromone

In order to favor a larger exploration and, more particularly, at the beginning of the search, Ant-Solver derives its features from the $\mathcal{MAX}$-$\mathcal{MIN}$ Ant System, i.e., pheromone trails are limited to an interval $[\tau_{\min}, \tau_{\max}]$ and are initialized to $\tau_{\max}$. Hence, after n cycles of Ant-Solver, the pheromone trail $\tau(i,j)$ on edge (i,j) is such that $(1-\rho)^n * \tau_{\max} \leq \tau(i,j) \leq \tau_{\max}$, where ρ is the pheromone evaporation parameter and usually has a value very close to zero. As a consequence, during the first cycles, pheromone trails have very similar values and do not significantly influence the computation of transition probabilities.

Fig. 5 illustrates this on four runs of Ant-Solver on a same random binary problem, with different values for α and ρ. This figure displays the evolution of the dispersion of the colony, i.e., the average distance between all pairs of constructed assignments for each cycle (where the distance between two assignments is defined as the number of different variable-value assignments). At the beginning of the search, the dispersion of the colony is very high: the assignments constructed take approximately 85% of different values. During this first phase,

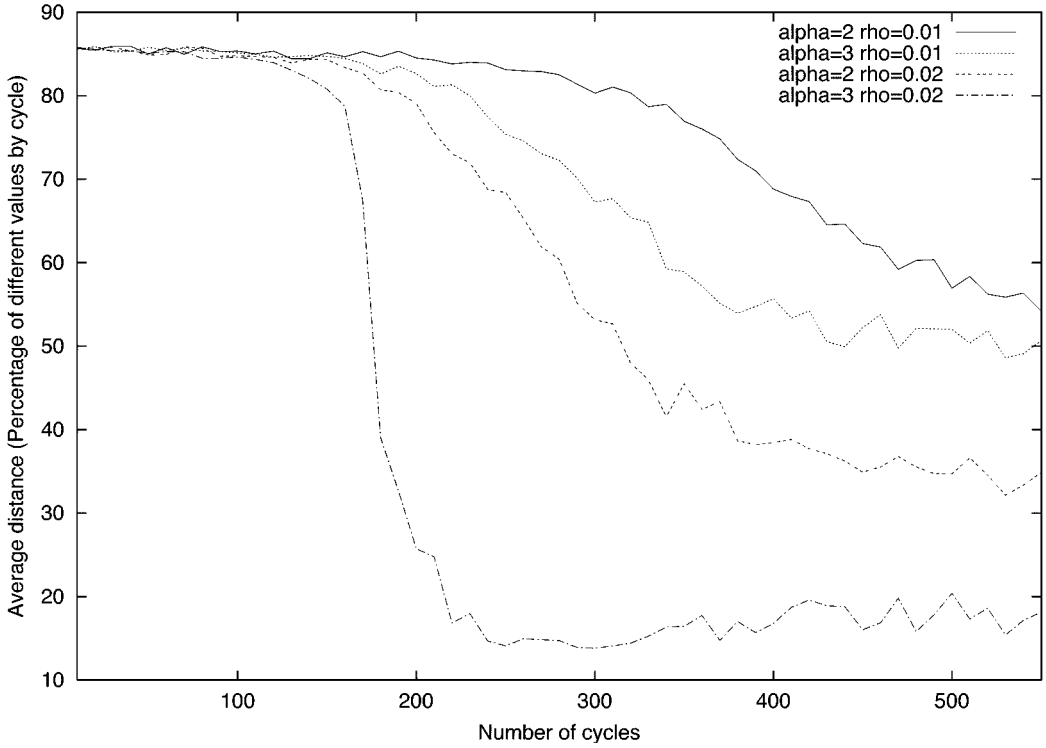

Fig. 5. Evolution of the dispersion of ants. Each curve displays results obtained for one run on a same $\langle 100, 8, 0.14, 0.23\rangle$ instance, with different values of α and ρ.

ants are not influenced by pheromones, and they explore the search space widely. Then, after a significant number of cycles, the average distance decreases progressively. During this second phase, ants are increasingly influenced by pheromones so that they converge and focus on a smaller area of the search space. Note that, for low values of α and ρ, the exploration phase is longer: when $\alpha = 2$ and $\rho = 0.01$, the dispersion starts to decrease slowly after 200 cycles, whereas when $\alpha = 3$ and $\rho = 0.02$, it decreases quickly and, after 200 cycles, it has already reached a very low value.

However, if the influence of pheromone is reduced deliberately at the beginning of the search in order to favor exploration, administrating pheromone is tedious and time consuming. Indeed, let us consider a CSP (X, D, C) and let $n = \mid X \mid$ be the number of variables and $q = \sum_{X_i \in X} \mid D(X_i) \mid$ be the number of vertices of the associated construction graph. To construct a complete assignment, the computation of pheromone values for all transition probabilities requires $\mathcal{O}(n*q)$ operations. Then, at the end of each cycle, pheromone laying requires $\mathcal{O}(n^2)$ operations for each rewarded assignment and pheromone evaporation requires $\mathcal{O}(q^2)$ operations. The other operations, which do not deal with pheromone, are the selection of variables, the computation of heuristic factors, and the local repair phase. The complexity of these operations mainly depends on the kind of constraints considered (e.g., global constraints, binary constraints, numerical constraints). However, when choosing appropriate data structures that allow incremental computations, the complexity of these operations is usually an order lower than $\mathcal{O}(q^2)$. Actually, when q increases, most of the computation time is used to administrate pheromone. For example, on $\langle 100, 8, 0.14, 0.23\rangle$ random binary CSPs, assignments are constructed nearly three times faster when pheromone is not used.

B. Description of the Preprocessing Step

The introduction of a preprocessing step is motivated by the fact that pheromone is rather expensive to administrate, whereas it has an effect on ants' search only after some 100 or so cycles. The idea is to collect a significant number of assignments by performing "classical" LS, i.e., by iteratively constructing complete assignments, without using pheromone, and repairing them. For easy problems that are far enough from the phase transition region, LS usually finds solutions quickly, so that this preprocessing step stops iterating on a success and the whole algorithm terminates. However, for harder problems within the phase- transition region, LS more often fails in finding a solution. In this case, the goal of the preprocessing step is to collect a representative set of assignments, thus constituting a kind of sampling of the search space. Then, we select from this sample set the best assignments and we use them to initialize pheromone trails. Finally, we continue the search with Ant-Solver.

We shall call $\mathrm{SampleSet}$ the set of all assignments constructed during the preprocessing step, n_{Best} the number of best assignments that are selected from $\mathrm{SampleSet}$ to initialize pheromone trails, and $\mathrm{BestOf}(n_{\mathrm{Best}}, \mathrm{SampleSet})$ the n_{Best} best assignments contained in $\mathrm{SampleSet}$.

To determine the number of assignments that should be collected in $\mathrm{SampleSet}$, one has to find a tradeoff between computing a large number of assignments, which is more

procedure preprocessing
  compute n_{Best} assignments and store them in *SampleSet*
  repeat
    $OldCost \leftarrow \sum_{\mathcal{A} \in BestOf(n_{Best}, SampleSet)} cost(\mathcal{A})$
    compute n_{Best} assignments and add them to *SampleSet*
    $NewCost \leftarrow \sum_{\mathcal{A} \in BestOf(n_{Best}, SampleSet)} cost(\mathcal{A})$
  until $NewCost/OldCost > 1 - \epsilon$ **or** a solution has been found

Fig. 6. Preprocessing step.

representative of the search space, and a smaller number of assignments, which is more quickly computed. Experiments show that the harder a problem is, the more assignments should be computed. Therefore, instead of fixing the number of assignments that should be computed in SampleSet, we only fix n_{Best}, the number of assignments that will be selected from SampleSet to initialize pheromone trails, and we introduce a limit ϵ on the quality improvement of these best assignments.

The preprocessing procedure is more precisely described in Fig. 6. This procedure iteratively collects assignments in SampleSet until the average cost of the n_{Best} best assignments in SampleSet has not been improved by more than a percentage given by ϵ. The assignments are computed by applying LS on complete assignments that are constructed according to the algorithm in Fig. 2, but where values are chosen with respect to quality factors only, i.e., the probability of choosing a value v for a variable X_j is $p_{\mathcal{A}}(\langle X_j, v\rangle) = \eta_{\mathcal{A}}(\langle X_j, v\rangle)^{\beta} / \sum_{w \in D(X_j)} \eta_{\mathcal{A}}(\langle X_j, w\rangle)^{\beta}$.

Finally, at the end of the preprocessing step, if no solution is found, the n_{Best} best assignments of SampleSet are used to initialize pheromone trails: the pheromone trail on each edge (i, j) of the construction graph is set to

$$\tau(i,j) \leftarrow \sum_{\mathcal{A}_k \in \text{BestOf}(n_{\text{Best}}, \text{SampleSet})} \Delta\tau(\mathcal{A}_k, i, j)$$

where $\Delta\tau(\mathcal{A}_k, i, j)$ is the quantity of pheromone deposited on edge (i, j) for assignment $\mathcal{A}_k$ as defined in Section III.

C. Experimental Study of the Preprocessing Step

The preprocessing step is parameterized by n_{Best}, the number of assignments that are extracted from the sample set to initialize pheromone trails, and ϵ, the limit on the quality improvement of the n_{Best} best assignments of the sample set. We studied the influence of these two parameters on $\langle 100, 8, 0.14, p_2\rangle$ instances (with the other parameters set to $\alpha = 2$, $\beta = 10$, $\rho = 0.01$ and $\text{nbAnts} = 8$). We performed experiments with different values of n_{Best} (ranging from 50 to 400) and ϵ (ranging from 0.005 to 0.03). With respect to running times, the best results are obtained with the highest values of ϵ and the smallest values of n_{Best}, on all the classes of problems. With respect to success rates, the best results are usually obtained with the smallest values of ϵ and the largest values of n_{Best}. However, we noticed that success rates often decrease when $n_{\text{Best}} \geq 300$. A good tradeoff between running time and success rate appears to be $n_{\text{Best}} = 200$ and $\epsilon = 0.02$.

Table I displays results obtained with Ant-Solver with MCH LS and preprocessing when $n_{\text{Best}} = 200$ and $\epsilon = 0.02$. One can notice that for easy problems many solutions are found during preprocessing, whereas for harder problems within the phase-transition region, only few solutions are found during preprocessing. Also, the number of assignments constructed during preprocessing increases with the hardness of instances. More experimental results are given in the next section.

TABLE I
RESULTS OBTAINED BY ANT-SOLVER WITH PREPROCESSING ON $\langle 100, 8, 0.14, p_2\rangle$ CSPS (WITH $n_{\text{Best}} = 200$ AND $\epsilon = 0.02$)

p_2	Success rate		Nb assign. built		CPU time spent	
	During prepro	After prepro	During prepro	After prepro	During prepro	After prepro
0.19	99.5	0.5	92	1	0.4	0.1
0.21	48.6	51.1	1401	197	11.0	6.1
0.23	0.5	95.0	1619	704	15.7	21.4
0.25	2.1	96.1	1502	355	15.3	11.0
0.27	65.7	34.3	763	8	8.3	0.4

For each value of p_2, the table displays the percentage of runs that have succeeded during preprocessing, the percentage of runs that have succeeded after preprocessing, the number of assignments constructed during preprocessing, the number of assignments constructed after preprocessing, the time spent for preprocessing, and the time spent after preprocessing.

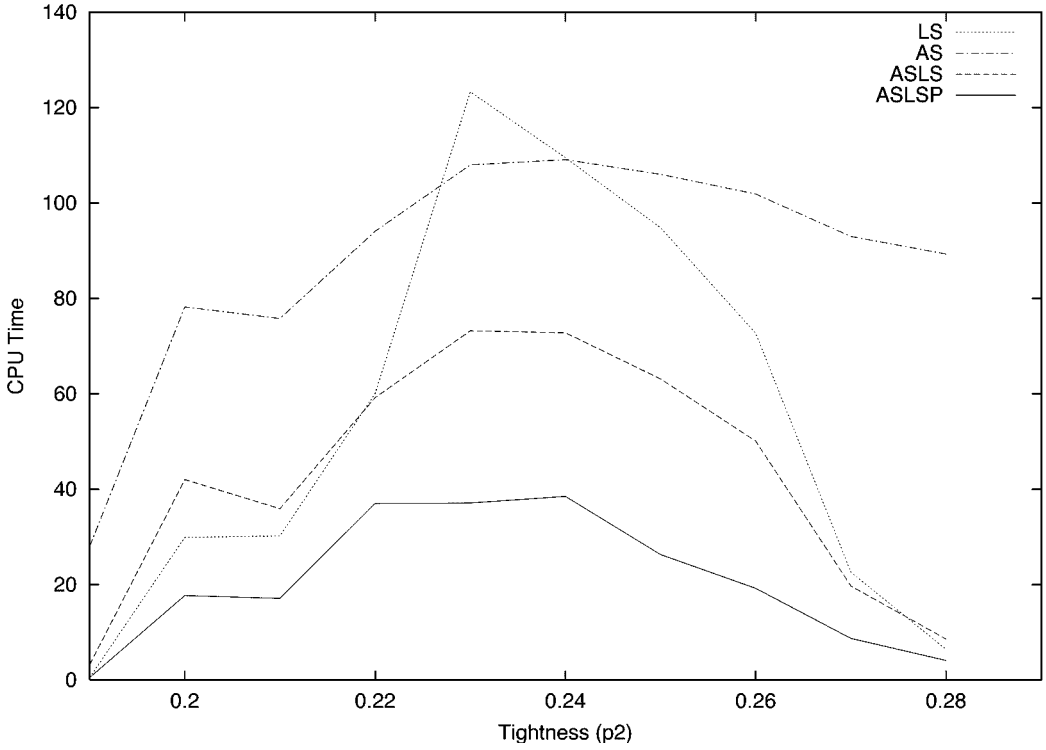
VI. EXPERIMENTAL RESULTS

We now experimentally compare the different algorithms that we have presented in this paper, i.e., Ant-Solver, MCH LS, Ant-Solver with MCH LS, and Ant-Solver with MCH LS and preprocessing. All these algorithms are implemented in C++. To solve a new CSP with one of these algorithms, one only has to implement a C++ class that describes the problem to be solved. This class specifies the number of variables, the number of values associated with each variable, the evaluation function (which returns the number of new unsatisfied constraints when assigning a value to a variable with respect to a partial assignment), the variable selection function, and the LS procedure.

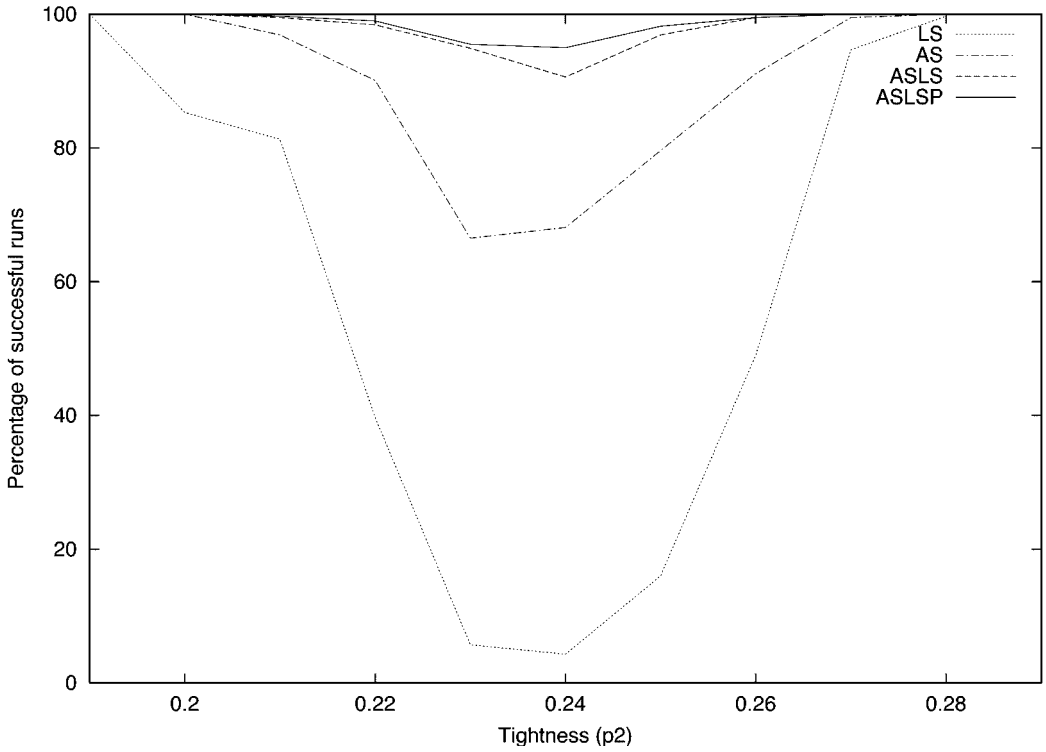
For Ant-Solver, Ant-Solver with MCH LS, and Ant-Solver with MCH LS and preprocessing, we set the parameters to $\alpha = 2$, $\beta = 10$, $\rho = 0.01$, and $\text{nbAnts} = 8$. For LS, Ant-Solver with MCH LS, and Ant-Solver with MCH LS and preprocessing, we used a LS procedure based on the MCH that stops iterating when the number of violated constraints is not improved after $\mid X \mid$ successive iterations. For Ant-Solver with MCH LS and preprocessing, we set n_{Best} to 200 and ϵ to 2%. For all algorithms, we used the smallest domain ordering to select at each step the next variable to assign. Finally, we limited all runs to 200 s of CPU time. All experiments were performed on a PC with an AMD Athlon Processor, 256-MB RAM, and 900 MHz.

Fig. 7 displays some experimental results obtained on $\langle 100, 8, 0.14, p_2\rangle$ random binary CSPs.[1] When considering success rates, one can remark that Ant-Solver with MCH LS and preprocessing is slightly more successful than Ant-Solver with MCH LS. This shows that the preprocessing step allows to solve a few more instances. Then, Ant-Solver with MCH LS and preprocessing and Ant-Solver with MCH LS are both much more successful than Ant-Solver. This shows that combining LS with Ant-Solver improves the solution process. Finally,

[1]We have also performed experiments on $\langle 100, 8, 0.05, p_2\rangle$ and $\langle 200, 8, 0.05, p_2\rangle$ binary CSPs and on graph coloring problems with three colors and from 200 to 600 vertices. On all these problems, we obtained results very similar to those displayed in Fig. 7.



(a)



(b)

Fig. 7. Comparison of MCH LS, Ant-Solver (AS), Ant-Solver with MCH LS (ASLS), and Ant-Solver with MCH LS and preprocessing (ASLAP) on $\langle 100, 8, 0.14, p_2 \rangle$ CSPs (average results on 300 instances for each value of p_2). (a) Success rates with respect to p_2. (b) CPU time (average on successful runs) with respect to p_2.

MCH LS is far less successful than Ant-Solver and it has hardly solved four percent of the hardest instances, when $p_2 = 0.24$.

When considering the time criterion, one can remark that Ant-Solver with MCH LS and Ant-Solver with MCH LS and preprocessing are always much more efficient than Ant-Solver. The benefit of providing ants with LS abilities is even more remarkable for tightly constrained instances that are beyond the phase-transition region, when $p_2 > 0.24$. For these instances,

LS is usually capable of finding a solution after the construction of very few assignments while ants slowly converge to the solution. Also, Ant-Solver with MCH LS and preprocessing is always much faster than Ant-Solver with MCH LS. This shows that preprocessing speeds up the solution process.

A. Experimental Comparison With Random Walk

The LS procedure considered in our first experiments is based on the greedy MCH, incapable of escaping from local optima. This LS procedure gives good results for instances that are far enough from the phase-transition region. However, it gives very poor results for instances within the phase-transition region, as the search space landscape of these instances contains many more local optima [3], [33].

To help it escape from local optima, greedy LS can be combined with different metaheuristics. We now compare our approach to the random walk MCH LS (RWLS), which is one of the best performing extensions of MCH [24], [32]. At each step, the RWLS procedure either randomly changes the value of a variable with probability p_{noise} or repairs a conflicting variable using the MCH with probability $1 - p_{\text{noise}}$. We set the probability p_{noise} of performing a random move to 0.07.[2]

First experiments on $\langle 100, 8, 0.14, 0.23 \rangle$ instances showed that RWLS clearly outperforms Ant-Solver: indeed, RWLS always finds a solution much faster than Ant-Solver. However, the RWLS performance is drastically degraded when the number of constraints is increased. This is illustrated in Table II, which reports experimental results obtained when increasing the connectivity probability p_1—that determines the number of constraints. We considered three classes of instances (all of them having 100 variables and eight values in each variable domain): when $p_1 = 0.3$, instances have around 1500 constraints, when $p_1 = 0.5$, instances have around 2500 constraints, and when $p_1 = 0.7$, instances have around 3500 constraints. For each value of p_1, we considered instances within the phase-transition region by setting p_2 in such a way that the constrainedness κ is equal to one (i.e., when $p_1 = 0.3$, $p_2 = 0.13$, when $p_1 = 0.5$, $p_2 = 0.08$, and when $p_1 = 0.7$, $p_2 = 0.06$).

Table II shows the evolution of success rates within successive running time limits by reporting the percentage of successful runs every 50 s. From this table, one can remark that, when $p_1 = 0.3$, RWLS finds solutions much faster than Ant-Solver: RWLS solves 87% of the instances in less than 50 s and 100% in less than 150 s, whereas Ant-Solver with MCH LS and preprocessing requires 300 s to solve all the instances. However, when the number of constraints increases, RWLS becomes much less successful. For example, when $p_1 = 0.7$, RWLS solves 10% of the instances, in less than 50 s, but then the success rate increases very slowly so that it has hardly solved half of the instances after 350 s. For these instances, Ant-Solver with MCH LS and preprocessing is much more successful and is capable of solving 99% of them within 350 s.

TABLE II
COMPARISON OF ANT-SOLVER WITH MCH LS, ANT-SOLVER WITH MCH LS AND PREPROCESSING, AND RWLS

Time	50	100	150	200	250	300	350
Results on $< 100, 8, 0.3, 0.13 >$ CSPs							
ASLS	0	13	72	94	98	100	100
ASLSP	4	59	91	96	99	100	100
RWLS	87	99	100	100	100	100	100
Results on $< 100, 8, 0.5, 0.08 >$ CSPs							
ASLS	0	0	15	79	95	97	98
ASLSP	0	23	87	98	99	99	99
RWLS	11	19	26	34	45	51	73
Results on $< 100, 8, 0.7, 0.06 >$ CSPs							
ASLS	0	0	5	21	51	78	93
ASLSP	0	4	24	56	81	94	99
RWLS	10	17	25	33	38	46	51

Each line successively displays the percentage of successful runs after 50, 100, 150, 200, 250, 300, and 350 s of CPU time (over 100 runs).

VII. CONCLUSION

We described in this paper Ant-Solver, a generic algorithm for solving CSPs based on the ACO metaheuristic. Pheromone is used to learn the global desirability of a set of variable-value assignments and it is used as a heuristic for choosing values when constructing an assignment. Experiments reported in this paper show that ants "alone," without LS abilities, are able to solve hard instances, although they are rather slow at finding solutions.

This ACO algorithm may be combined with any LS procedure, thus boosting performances of both approaches. For all experiments reported in this paper, we used the MCH for LS. Further work will concern the integration in Ant-Solver of other greedy LS heuristics (such as GSAT [25]), but also of LS procedures capable of escaping from local minima (such as tabu search [15] or random walk). Indeed, experimental comparisons of Ant-Solver with RWLS reported in Section VI show that these approaches have complementary features: RWLS can find solutions to some problems very quickly, while it fails solving others; Ant-Solver requires more time to converge, but it actually solves many more instances. Therefore, the combination of RWLS with Ant-Solver could allow one to take advantage of both features.

In this paper, we also introduced a preprocessing step that favors, at a lower cost, a larger exploration of the search space at the beginning of the search. The idea is to initialize pheromone trails with respect to a representative sample of the search space. We showed on random binary CSPs that this preprocessing step improves the solution process, both with respect to success rates and running times. This preprocessing step could be introduced as well in other ACO algorithms and it would be interesting to evaluate its use on other problems, like the traveling salesman problem or the quadratic assignment problem.

A main motivation of this paper was to provide a generic tool that can be used to solve any CSP: to solve a new problem with Ant-Solver, one only has to implement a C++ class that describes the variables, their domains, the evaluation function, and the LS procedure. However, an efficient implementation of this class is not always straightforward. In particular, one has to introduce appropriate data structures so that the number of constraints violated can be evaluated incrementally when constructing assignments or when repairing them by LS. Actually, Ant-Solver could be integrated within a modeling language for LS, such as Localizer [22]. Such a language would allow one to design efficient and incremental procedures for LS more easily.

[2]We made experiments with different values of p_{noise} ranging from 0.01 to 0.1. The best results were obtained when $p_{\text{noise}} = 0.07$.

A drawback of the genericity of Ant-Solver is that, on some particular problems, it may be less efficient than specialized algorithms dedicated to these problems. In particular, many CSPs involve global constraints, e.g., "AllDiff" constraints (that constrain a set of variables to take different values) or "AtMost" constraints (that fix the maximal number of variables that may take a given value). To handle such global constraints, one can translate them into an equivalent set of simpler constraints and then use Ant-Solver. However, one usually obtains better results when using specialized algorithms for these global constraints. For example, in [29], we have described an ACO algorithm for handling permutation constraints (that constrain a set of n variables to be assigned with a permutation of n known values). Many CSPs involve such global permutation constraints, e.g., the n queens, the all-interval series problem, and the car-sequencing problem [28]. For these particular constraints, we have introduced a dedicated graph that is much smaller than the construction graph used in Ant-Solver, which takes permutation constraints into account in an *a priori* way, so that the search space is reduced and solutions are found quicker. Hence, further work will also concern the integration of dedicated graphs within Ant-Solver in order to deal more efficiently with such global constraints.

ACKNOWLEDGMENT

The author would like to thank M. Dorigo and the referees for their fruitful comments on preliminary versions of this paper.
